

# Removing Artefacts From Color and Contrast Modifications

Julien Rabin, Julie Delon, and Yann Gousseau

**Abstract**—This work is concerned with the modification of the gray level or color distribution of digital images. A common drawback of classical methods aiming at such modifications is the revealing of artefacts or the attenuation of details and textures. In this work, we propose a generic filtering method enabling, given the original image and the radiometrically corrected one, to suppress artefacts while preserving details. The approach relies on the key observation that artefacts correspond to spatial irregularity of the so-called *transportation map*, defined as the difference between the original and the corrected image. The proposed method draws on the nonlocal Yaroslavsky filter to regularize the transportation map. The efficiency of the method is shown on various radiometric modifications: contrast equalization, midway histogram, color enhancement, and color transfer. A comparison with related approaches is also provided.

**Index Terms**—Artefact-free, color transfer, contrast adjustment, contrast equalization, contrast modification, histogram specification, image regularization, optimal transportation.

## I. INTRODUCTION

APPLYING contrast changes to digital images is one of the most elementary tools for image enhancement. Such changes may be obtained by applying a prescribed function to the gray values of images, as in contrast stretching or Gamma correction, or by prescribing the histogram of the resulting image, as in histogram equalization or specification from an example image [1]. Such operations are characterized by the way they affect the histogram of an image and may be seen as modifications of their gray-level distribution. These techniques extend to color images by considering a luminance channel, as in Gamma correction, or by working on each color channel separately. The prescription of the 3-D color distribution is more satisfying because it avoids the creation of false colors, but is also more involved. Actually, a nice theoretical framework enabling to merge the gray level and color cases is the one of optimal transportation, also known as the Monge–Kantorovich

Manuscript received July 23, 2010; revised February 09, 2011; accepted March 31, 2011. Date of publication April 15, 2011; date of current version October 19, 2011. problem [2], as we will briefly recall in this paper. When the resulting color histogram is prescribed by a target image, one speaks of *color transfer*. Various approaches to this task are proposed in [3]–[6].

Applications of contrast or color changes are of course extremely numerous. With the popularization of digital photography, these techniques have become immensely popular through the use of various “curves” in image editing software. Early uses of contrast equalization are the enhancement of medical images [7] and the normalization of texture for analysis purposes [8]. In a related direction, the construction of *midway histograms* [9], [10] is useful for the comparison of two images of the same scene. More recently, extensive campaigns of old movies digitization have claimed for the development of contrast modification techniques to correct flicker [11], [12]. Similar techniques are commonly used in the postproduction industry [13], [14]. Another field of increasing industrial interest in which contrast changes play a central role is the one of imaging in bad climatic conditions, see, e.g., [15]. Color modification or transfer is also useful for a wide range of applications, such as aquatic robot inspection [16], space image colorization [17], and enhancement of painting images.

A common drawback of most methods aiming at modifying the contrast or color content of images is their strong tendency to create visual artefacts. Indeed, when increasing the contrast, parasite structures that were barely visible become prominent. Most noticeable is the enhancement of noise and compression scheme patterns, such as “block effect” due to the JPEG standard. In the other direction, contrast reduction or color transfer may yield detail loss and texture washing. A last artefact is particularly noticeable in the case of color transfer and appears when the proportions of colors are very different between images. The goal of this paper is to propose a universal approach to remove those artefacts. This approach can be used as a post-processing for many classical image modification tasks, such as contrast and color transfer, movie restoration, gamut mapping, or high-dynamic-range (HDR) image visualization.

Before proceeding, we now recall some of the approaches that have been proposed in the literature to suppress artefacts due to contrast or color modification. The simplest one is proposed in [18] in the context of local histogram modifications and amounts to limit the modification depending on gradient values. While improving the results in some cases, this approach let most artefacts untouched. In [5], it is proposed to correct color transfer artefacts by using a variational regularization after the transfer. Still in a variational framework, the authors of [10] propose a unified formulation containing both color transfer and regularity constraints in a single energy minimization. For the problem of color proportion, a possible approach is to transfer color after

having identified some homogeneous regions, as proposed in [6] and [19]. A related class of works takes interest in the avoidance of compression artefacts, usually using the properties of the compression scheme, see, e.g., [20].

In this paper, we propose to remove all the artefacts described above by regularizing the *transportation map*, defined as the image of the differences between the original image and the one after contrast or color modification. Indeed, we will show that all these artefacts may be interpreted as spatial irregularities of this transportation map. In order to regularize this map without introducing blur in the final image, we take inspiration from nonlocal methods [21] that have been proposed for image denoising and more precisely from the Yaroslavsky filter [22]. The transportation map is filtered by averaging pixel values using weights that are computed on the original image, therefore adapting to the geometry of this initial image. It will be shown that artefacts are progressively suppressed by iterating this filtering stage and that the proposed filter generally provides better results than the approaches described in the previous paragraph. This paper is organized as follows. In Section II, the general setting for contrast and color modifications is introduced. The generic approach proposed in this work is given in Section III, and experiments are displayed in Section IV. In the Appendices, useful facts and results about optimal transportation and powers of stochastic matrices are given.

## II. COLOR AND CONTRAST MODIFICATION

Here, we recall how color and contrast modifications can be applied to images and why they are likely to create visual artefacts.

### A. Contrast or Color Distribution of an Image

Let  $u : \Omega \mapsto \mathbb{R}^n$  be a discrete image, with  $n = 1$  for a gray-level image,  $n = 3$  for a color image, and where  $\Omega \subset \mathbb{Z}^2$  is the bounded image domain. Assume that  $u$  takes its values in the set  $\{y_1, \dots, y_P\} \subset \mathbb{R}^n$ , and then the gray level or color distribution of  $u$  is defined as

$$h_u = \sum_{i=1}^P h_i \delta_{y_i} \quad (1)$$

where  $h_i = (1/|\Omega|) |\{x \in \Omega; u(x) = y_i\}|$ . When  $n = 1$ , we denote by  $H_u$  the cumulative distribution function of  $h_u$ . The distribution  $h_u$  is also called the gray level or color histogram of  $u$  and  $H_u$  is called its cumulative histogram.

### B. Color and Contrast Modifications

It is usual to apply simple radiometric transformations to a gray-level image in order to improve its contrast and level of details. Such transformations generally consist in an increasing function  $T$ , in order to preserve gray level ordering. The image  $u$  becomes  $T(u)$ , and its gray level distribution becomes  $h_{T(u)} = \sum_{i=1}^P h_i \delta_{T(y_i)}$ . Particular cases of such transformations are histogram stretching ( $T(x) = ax + b$ ) or histogram clipping ( $T(x) = \min(\beta, \max(\alpha, x))$ ), used for instance to improve visualization in satellite or medical imaging [7]. Another example is the function  $T(x) = \log(1 + x)$ , which is particularly useful to visualize images of Fourier transforms or

HDR images [23]. Similar transformations can also be applied to the luminance channel of a color image [see an example of histogram clipping in Fig. 1(e)]. Note that some other methods have been developed for local contrast enhancement, e.g., making use of the Curvelet transform [24], of a variational framework [14], or of a PDE formalism [25].

In some cases, it is useful to assign to an image  $u$  a given target distribution  $f$ . This amounts to find a mapping  $T$  (called contrast or color transfer) such that the distribution of  $T(u)$  is equal or at least close to  $f$ , i.e., such that

$$h_{T(u)} \simeq f. \quad (2)$$

Most of the time, the equality cannot be exactly satisfied. For instance, if  $h_u = \delta_{1/2}$  ( $u$  is a constant image) and  $f = (1/2)(\delta_0 + \delta_1)$ , there is no mapping  $T$  such that the distribution of  $T(u)$  is exactly  $f$ .  $T$  is thus generally chosen so that  $h_{T(u)}$  be close to  $f$  in some sense.

For  $n = 1$ , (2) can be satisfied in the sense that the cumulative distribution functions  $H_{T(u)}$  and  $F$  coincide on the values taken by  $T(u)$ . This is always possible in the continuous setting (i.e., when  $F$  is continuous). Now, if we add the constraint that  $T$  is increasing, the solution is given by

$$T = F^{-1} \circ H_u \quad (3)$$

where  $F^{-1}$  is defined as  $F^{-1}(t) = \inf\{\lambda \in \mathbb{R}; F(\lambda) \geq t\}$ . If  $f$  is a constant distribution on the range of  $u$ , (3) yields the well-known *histogram equalization*. More generally, if  $f$  is the gray-level distribution  $h_v$  of another image  $v$ , then  $T = H_v^{-1} \circ H_u$  is called *histogram specification*. These transformations can also be applied to the luminance channel of a color image [an example is displayed in Fig. 1(b)]. Some variants of this framework have been proposed to apply such equalization locally [18], [26] [see Fig. 1(c) and 1(d)] or with a data-fidelity term [27].

When  $n \geq 2$ , the interpretation of (2) is less clear and the monotonic constraint cannot be used anymore to find an optimal mapping  $T$ . A naive solution, proposed in [3] in the case of color images, consists in applying an affine transformation to the color distribution of  $u$  in order to match the mean and variance of the color distribution  $f$ . If this elementary solution can be satisfying for cases involving images having similar and simple color distributions, it usually fails in general cases. In order to find a satisfying mapping in the general case, the problem must be seen in the framework of optimal transport, as described in more details in Appendix A. If  $n = 1$ , this framework leads to formulas similar to (3) for histogram equalization and specification. If  $n \geq 2$ , however, no analytic formulation can be found for the optimal mapping  $T$ . Such mappings can be estimated numerically, for instance by using the simplex algorithm. Most of the time, this estimation leads to expansive computations. In practice, a common approximation is to perform an histogram specification separately on the three channels of the color image (see, e.g., [28]). Though, a more satisfying approximation can be computed by estimating iteratively 1-D optimal mappings on random axes, as proposed in [5] and studied in [29] [an illustration is proposed in Fig. 1(m)]. The result is fast to compute,

Fig. 1. Examples of visual artefacts produced by different image processing techniques and the corresponding regularizations. The first row exhibits several images resulting from different contrast enhancement methods applied to the same original image (a). The second row shows the corresponding applications of the TMR filter proposed in this paper. The third row shows an example of color transfer [the colors of (l) are affected to (k)]. Resulting artefacts are visible on (m) and are shown to be removed by the TMR filtering in (n). The fourth row shows corresponding details illustrating the various artefacts and their removal. Note: All of the images in this paper are much better appreciated when viewed full size from the electronic version of this article. All examples are available at: [http://perso.telecom-paristech.fr/~delon/artefact\\_removal\\_html/](http://perso.telecom-paristech.fr/~delon/artefact_removal_html/).

although not perfectly optimal in the sense of the Monge–Kantorovich transport problem described in Appendix A.

### C. Visual Artefacts

As it can be observed from the several examples provided in Fig. 1, four major visual artefacts can be caused by contrast or color modifications.

- **Noise enhancement:** this happens if the variance of the noise in  $u$  increases after the application of  $T$  to  $u$ , as illustrated for instance in Figs. 1(b) and 2(d) for histogram equalization.
- **Compression artefacts:** these artefacts appear when the original image  $u$  is the result of some compression scheme (e.g., JPEG) and when pixels with similar colors are mapped to different colors [see, e.g., Fig. 1(o)].

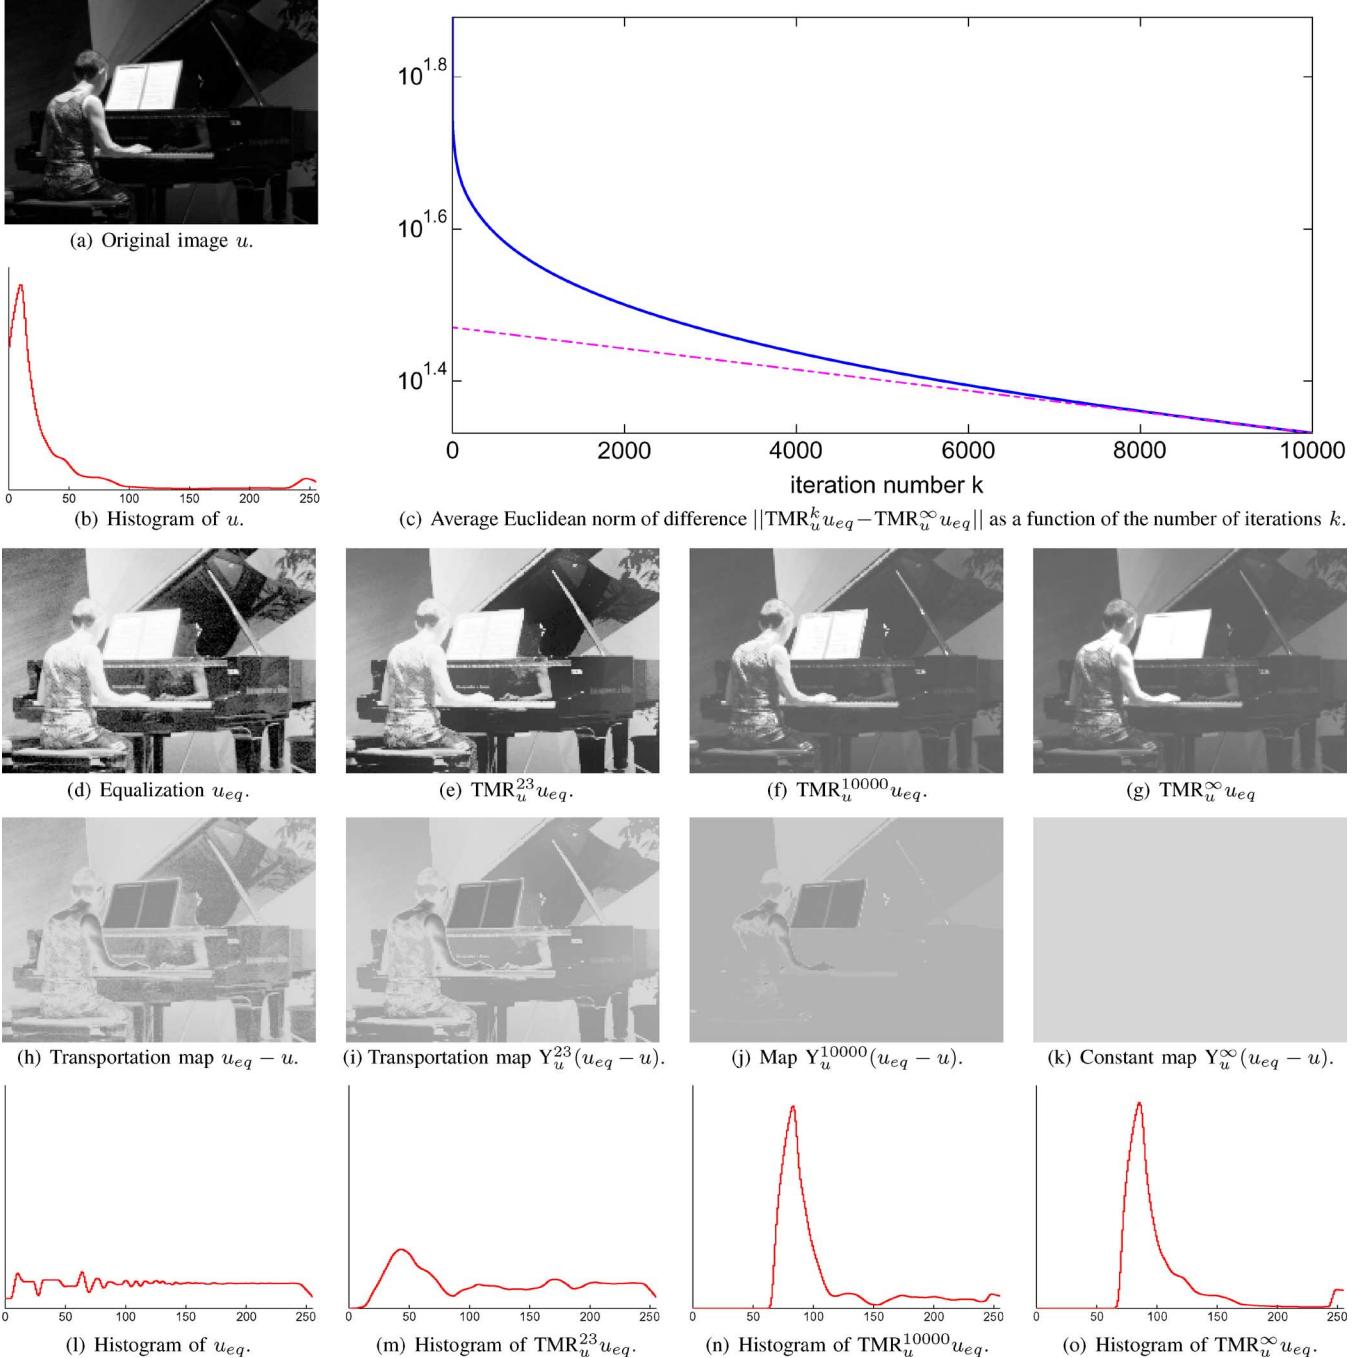

Fig. 2. Convergence study of the iterated TMR filter. (a) Low-dynamic-range image  $u$  and (b) its gray-level histogram. (d) Image  $u_{eq}$ , obtained by applying an histogram equalization to  $u$ , and (l) histogram of  $u_{eq}$ . (e)–(g) Iterations of the TMR filter, with (e) 23 iterations (corresponding to the automatic stopping criterion), (f) 10 000 iterations, and (g) convergence. (m)–(o) Corresponding gray-level histograms. (i)–(k) Corresponding transportation maps. Observe how the 23 iterations chosen by the stopping criterion permit to reduce the noise level while preserving contrast and image details.

- **Detail loss:** this results from a reduction of contrast between  $u$  and  $T(u)$  and can be observed for instance on the head of the bird in Fig. 1(p).
- **Color proportion inconsistencies:** Ideally, the mapping  $T$  should be defined in such a way that pixels having similar colors in the original image are mapped to similar colors. However, this is unfeasible if the proportions of colors are very different in the original and the target distributions, as illustrated by Figs. 1(q) and 6(i).

Our approach to remove these artefacts relies on the observation that they are all due to spatial irregularities of the trans-

portation map of the image  $u$ , defined as  $T(u) - u$ . Indeed, when comparing the geometrical information of the transportation map [see, e.g., Fig. 6(j)] with the one of the original color map, each of the aforementioned artefacts appears as an irrelevant high frequency feature. As a result, a piecewise constant transportation map [cf. the instance in Fig. 6(k)] taking into account the geometry of the image will considerably reduce artefacts from color and contrast modification. In this paper, the proposed solution to obtain such a desired transportation map consists in applying a guided edge-preserving filter to the transportation map, using the original image.

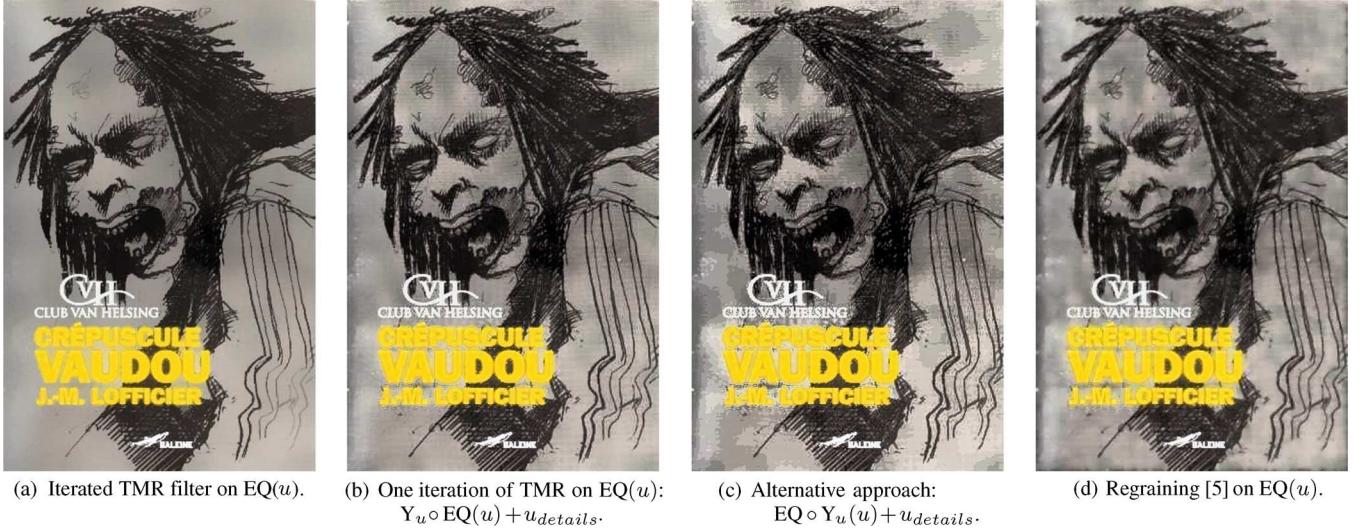

Fig. 3. Comparison of the iterated TMR filter with other regularization techniques for contrast enhancement. We consider here the image  $u$  and its equalization  $\text{EQ}(u)$  previously shown in Fig. 1(a) and (b), respectively.

### III. NEW REGULARIZATION APPROACH FOR TRANSPORTATION MAPS

Following the observations of the previous section, we propose to spatially filter the transportation map. The solution we chose is inspired from nonlocal filters [21]. This concept has been introduced for image denoising by Yaroslavsky [22]. Similar filters have been independently defined, as *SUSAN* [30] or the *Bilateral Filter* [31]. More recently, a somehow radical extension of this approach, the so-called ‘‘Non-Local Mean’’ filter [21] has been shown to outperform many approaches to image denoising. In what follows, we will make use of a variant of the Yaroslavsky filter to regularize transportation maps.

#### A. Transportation Map Regularization

Recall that  $T(u)$  is the image after color or contrast modification. In what follows, we write  $\mathcal{M}(u) := T(u) - u$  for the transportation map of image  $u$ . We propose to regularize it thanks to the operator  $Y_u$ , a weighted average with weights depending on the similarity of pixels in the original image  $u$ . The effect of this operator on an image  $v : \Omega \mapsto \mathbb{R}^n$  with  $n \geq 1$  is defined as

$$\mathbf{Y}_u(v) : x \in \Omega \mapsto \frac{1}{C(x)} \int_{y \in \mathcal{N}(x)} v(y) \cdot w_u(x, y) dy$$

with weights  $w_u(x, y) = e^{-\frac{\|u(x) - u(y)\|^2}{\sigma^2}}$  (4)

where  $\|\cdot\|$  stands for the Euclidean distance in  $\mathbb{R}^n$ , where  $\mathcal{N}(x) = x + \mathcal{N}(0) \subset \Omega$ , with  $\mathcal{N}(0)$  a spatial neighborhood of 0, where  $\sigma$  is a tuning parameter of the method and  $C(x)$  is the normalization constant  $C(x) = \int_{y \in \mathcal{N}(x)} w_u(x, y) dy$ .

Observe that if we apply  $Y_u$  to the image  $u$ , we obtain the Yaroslavsky filter [22]. If the weights also decrease as a function of the distance to  $x$ ,  $Y_u$  becomes similar to the *cross bilateral filter* introduced in [32] for flash photographic enhancement.

The regularization of the image  $T(u)$ , referred to as transportation map regularization (TMR), is then defined as

$\text{TMR}_u(T(u)) := u + \mathbf{Y}_u \mathcal{M}(u)$ . Now, observe that this formulation can be divided in two terms as

$$\text{TMR}_u(T(u)) = \underbrace{\mathbf{Y}_u(T(u))}_{\text{filtering of image } T(u)} + \underbrace{u - \mathbf{Y}_u(u)}_{\text{image detail}}. \quad (5)$$

First, the image  $T(u)$  is filtered by a nonlocal operator  $Y_u$ , following the regularity of the image  $u$ . This operation attenuates noise, compression, and color proportion artefacts but also the details of the image  $T(u)$ . The second operation performed by the TMR filter consists in adding the quantity  $u_{\text{details}} = u - \mathbf{Y}_u(u)$ , which can be considered as details of the original image (e.g., texture and fine structures). We will see in the experimental section that these two steps are very important to obtain a natural rendering of the image.

#### B. Properties

The previously defined filter has several nice properties which enable us to reduce the visual artefacts described in Section II-C.

First, observe that this filter leaves all the images  $u + \lambda, \lambda \in \mathbb{R}^n$ , unchanged. Moreover, if the application  $T$  consists of a multiplication by a positive constant  $\alpha$ , then  $\text{TMR}_u(\alpha u) = \alpha u + (1 - \alpha) \cdot u_{\text{details}}$ . If  $\alpha > 1$ , the transfer  $T$  increases the contrast. In that case, the TMR filter reduces the noise contained in the image difference  $u_{\text{details}}$ . If  $\alpha < 1$  the transfer  $T$  decreases the contrast and the TMR filter restores the lost details contained in  $u_{\text{details}}$ .

Finally, another interesting aspect of the TMR filter is that the discrete distribution of the regularized image  $\text{TMR}_u(T(u))$  is contained in the convex hull of the specified distribution of  $T(u)$ . This property somewhat prevents the creation of false colors which may be caused by the regularization process.

#### C. Iteration of TMR and Convergence Study

In practice, more than one iteration of the TMR filter is required to remove all the aforementioned artefacts. The image  $T(u)$  after  $k$  iterations of the TMR filter can be written as follows:

$$\text{TMR}_u^k(T(u)) := \mathbf{Y}_u^k(T(u) - u) + u$$

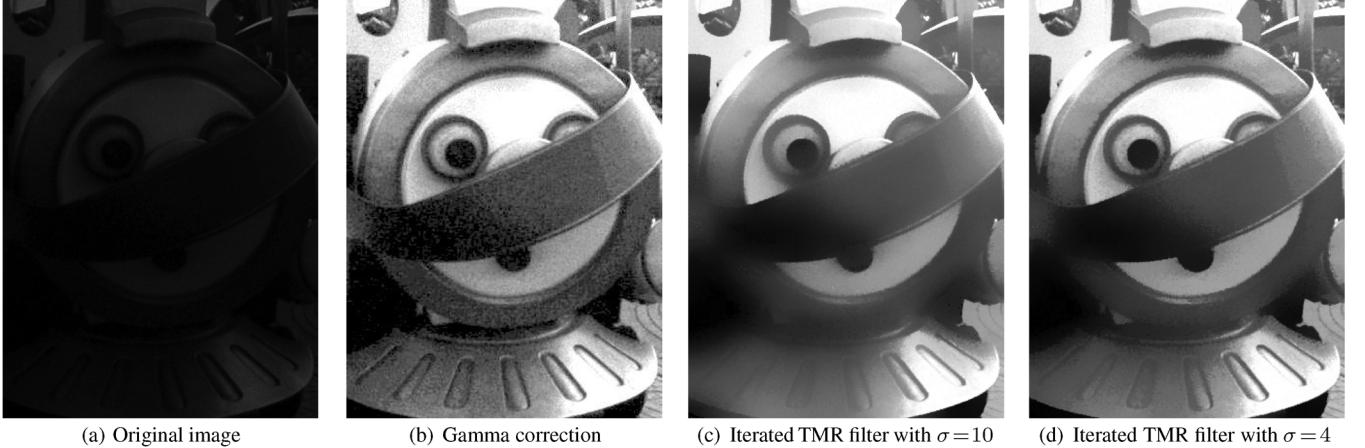

Fig. 4. Application of the iterated TMR filter for Gamma correction. (a) Gray-level image and (b) its contrast enhancement via histogram clipping and Gamma correction (with  $\gamma$  set to 1/2). Result of the iterated TMR filter, respectively, with (c)  $\sigma = 10$  and (d)  $\sigma = 4$ .

where  $\mathbf{Y}_u^k$  refers to the recursive use of the  $\mathbf{Y}_u$  filter. An illustration for histogram equalization is given in Fig. 3(b) and (a), where the equalized image [Fig. 1(b)] is regularized using respectively one and several iterations of the TMR filter.

The question is then how to choose the right number of iterations  $k$  and one may wonder what happens for large values of  $k$ . Studying the limit of  $\mathbf{Y}_u^k$  when  $k \rightarrow \infty$  boils down to the study of the limit of the powers of a matrix. Indeed, let us resize the discrete image  $u$  into a column vector  $v$  of size  $m$ . In this setting, the linear filter  $\mathbf{Y}_u$  can be written as an  $m \times m$  matrix  $A$ , whose coefficients are

$$A_{i,j} = \frac{w_u(i,j) \cdot \mathbb{1}_{j \in \mathcal{N}(i)}}{\sum_{k=1}^m w_u(i,k) \cdot \mathbb{1}_{k \in \mathcal{N}(i)}}, \quad 1 \leq i, j \leq m. \quad (6)$$

In this formulation,  $i$  is the index in the vector  $v$  of a pixel  $x$  in  $u$ , and  $\mathcal{N}(i)$  is the set of indexes in  $v$  corresponding to the 2-D neighborhood  $\mathcal{N}(x)$  in  $u$ . If we resize the map  $T(u) - u$  into the vector  $w$ , then  $\mathbf{Y}_u^k(T(u) - u)$  corresponds to the vector  $A^k w$ . Now, observe that the matrix  $A$  is stochastic, i.e., that  $A_{i,j} \geq 0, \forall i, j$  and  $\sum_{j=1}^m A_{i,j} = 1, \forall i$ . If we assume that  $A$  is primitive, i.e., that  $A^r$  is strictly positive for some  $r \in \mathbb{N}^*$  [and this is clearly true if the neighborhoods  $\mathcal{N}(x)$  are disks of radius  $\rho > 1$  in (4)], the Perron–Frobenius theorem permits to conclude that  $A^k$  tends toward a stochastic matrix  $A^\infty$  when  $k \rightarrow +\infty$ , and that all of the lines of  $A^\infty$  are equal (see Appendix B). This means that the map  $\mathbf{Y}_u^k(T(u) - u)$  tends toward a constant image  $\mathbf{Y}_u^\infty(T(u) - u)$ . In other words, the limit image  $\text{TMR}_u^\infty(T(u))$  is only a shift of the image  $u$  by a constant color.

The Perron–Frobenius theorem also gives information on the convergence rate of  $A^r$  towards  $A^\infty$ . More precisely, we know that  $A^r - A^\infty$  behaves as  $O(|\lambda|^r r^{m(\lambda)-1})$ , where  $\lambda$  is the eigenvalue of  $A$  with the second largest modulus and where  $m(\lambda)$  is the algebraic multiplicity of  $\lambda$ . In practice,  $|\lambda|$  is generally close to 1 for a similarity matrix  $A$ , and the resulting convergence rate is quite slow, as it will be confirmed in the experimental section. The aim of the next section is to propose a way to stop automatically the iterations of the filter TMR.

#### D. Stopping Criterion

In order to control the iterations of the TMR filter, we compute at each iteration a convergence map, written  $\mathcal{C}$  and defined at each pixel as follows:

$$\mathcal{C}(x) = \|\mathbf{Y}_u^k \mathcal{M}(u(x)) - \mathbf{Y}_u^{k-1} \mathcal{M}(u(x))\|$$

where  $\|\cdot\|$  is the average Euclidean norm in  $\mathbb{R}^n$ . We then consider that there is numerical convergence in pixel  $x$  when  $\mathcal{C}(x) < t$ , and the TMR filter is only applied to pixels for which the convergence map is greater than the threshold  $t$ . In all experiments, the convergence threshold has been set equal to  $t = 1$  (for  $n \times 8$ -bit images).

In practice, if  $x$  is the first pixel to attain this numerical convergence, this boils down to replace the line corresponding to  $x$  in matrix  $A$  by the same line in the identity matrix. The new matrix  $A_1$  is then iterated until a second pixel attains numerical convergence, and  $A_1$  is then replaced by  $A_2$ , etc. Observe that each matrix  $A_j$  is stochastic and such that  $A_j^k$  converges when  $k \rightarrow +\infty$  (see Appendix C for a proof), which implies that a new pixel attains numerical convergence after a finite number  $k_j$  of iterations. The whole process hence stops once all pixels satisfy  $\mathcal{C}(x) < t$ . At the end, if  $v$  is the vector corresponding to  $T(u) - u$ , we get

$$v^\infty = A_{n-1}^{k_{n-1}-1} \dots A_1^{k_1} A^{k_0} \cdot v. \quad (7)$$

Observe that the proposed stopping criterion permits also to save computation time since the iterations of the TMR filter concern fewer and fewer pixels.

## IV. EXPERIMENTAL STUDY

This section presents several applications of the TMR filter. Observe that this filter relies on two different parameters. The most important one is  $\sigma$ , which is used to compute the weighting terms in the computation of the regularized map [(4)]. In the following experiments, we have used  $\sigma = 10$ . The second parameter is related to the size of the neighborhood  $\mathcal{N}(x)$ . In experiments, we used disks of radius  $\rho = 10$ .

Fig. 5. Application of the iterated TMR filter to flicker stabilization. (a) Sequence of three images corrupted by flicker (strong and fast local contrast change). (b) Flicker stabilization results with the method of Delon and Desolneux [12]. Observe that the contrast is well harmonized over the sequence, but some artefacts related to brutal and local contrast modifications appear. (c) Same frames after local flicker reduction and application of the TMR filter. Iterated TMR filter permits to remove those artefacts.

#### A. Convergence Study

This paragraph illustrates the interest of the stopping criterion introduced in Section III-D. Consider the image  $u$  of Fig. 2(a). This image has a narrow dynamic range, as illustrated by its histogram [Fig. 2(b)]. Applying a histogram equalization to  $u$  yields an image  $u_{eq}$  with a more satisfying dynamic range but also increases the noise level [Fig. 2(d)]. Using the stopping criterion proposed in Section III-D, 23 iterations of the TMR filter are required to converge in the sense of (7). This permits to reduce dramatically the noise level while preserving the contrast and details of  $u$  [Fig. 2(e) and (m)].

The asymptotic behavior of the iterated TMR filter without using this stopping criterion is illustrated by Fig. 2(e)–(o). In accordance with the convergence study of Section III-C, we observe that the map  $Y_u^k(u_{eq} - u)$  tends toward a constant map  $Y_u^\infty(u_{eq} - u)$ <sup>1</sup> when  $k$  increases. The convergence rate is illustrated by Fig. 2(c), which plots the values of the norm  $\|TMR_u^k(u_{eq}) - TMR_u^\infty(u_{eq})\|$  when  $k$  increases. As expected, this convergence rate is very slow. This confirms that, while

the threshold on the convergence is important in practice, its precise setting is not crucial.

#### B. Contrast Modification

In this section, we investigate different applications of contrast modification to illustrate the interest of the proposed approach. In this context, we propose in Section IV-B3 a comparative study of our scheme with different regularization approaches that have been proposed in the literature.

1) *Histogram Modification:* The first lines of Fig. 1 illustrate the interest of the TMR filter for several contrast enhancement techniques, namely histogram equalization [Fig. 1(b) and (g)], spatial adaptive histogram equalization [18] [Fig. 1(c) and (h)] shape-preserving equalization [26] [Fig. 1(d) and (i)] and histogram clipping [Fig. 1(e) and (j)]. Notice how the artefacts described in Section II-C are present in these examples, in particular the enhancement of both noise and compression artefacts. In each case, the iterated TMR filter permits to remove these artefacts while preserving contrast and restoring details [see, e.g., Fig. 1(f)].

In Fig. 4, a challenging example of contrast modification using both histogram clipping and Gamma correction is given,

<sup>1</sup>The limit map can be computed explicitly in our case; see Appendix B.

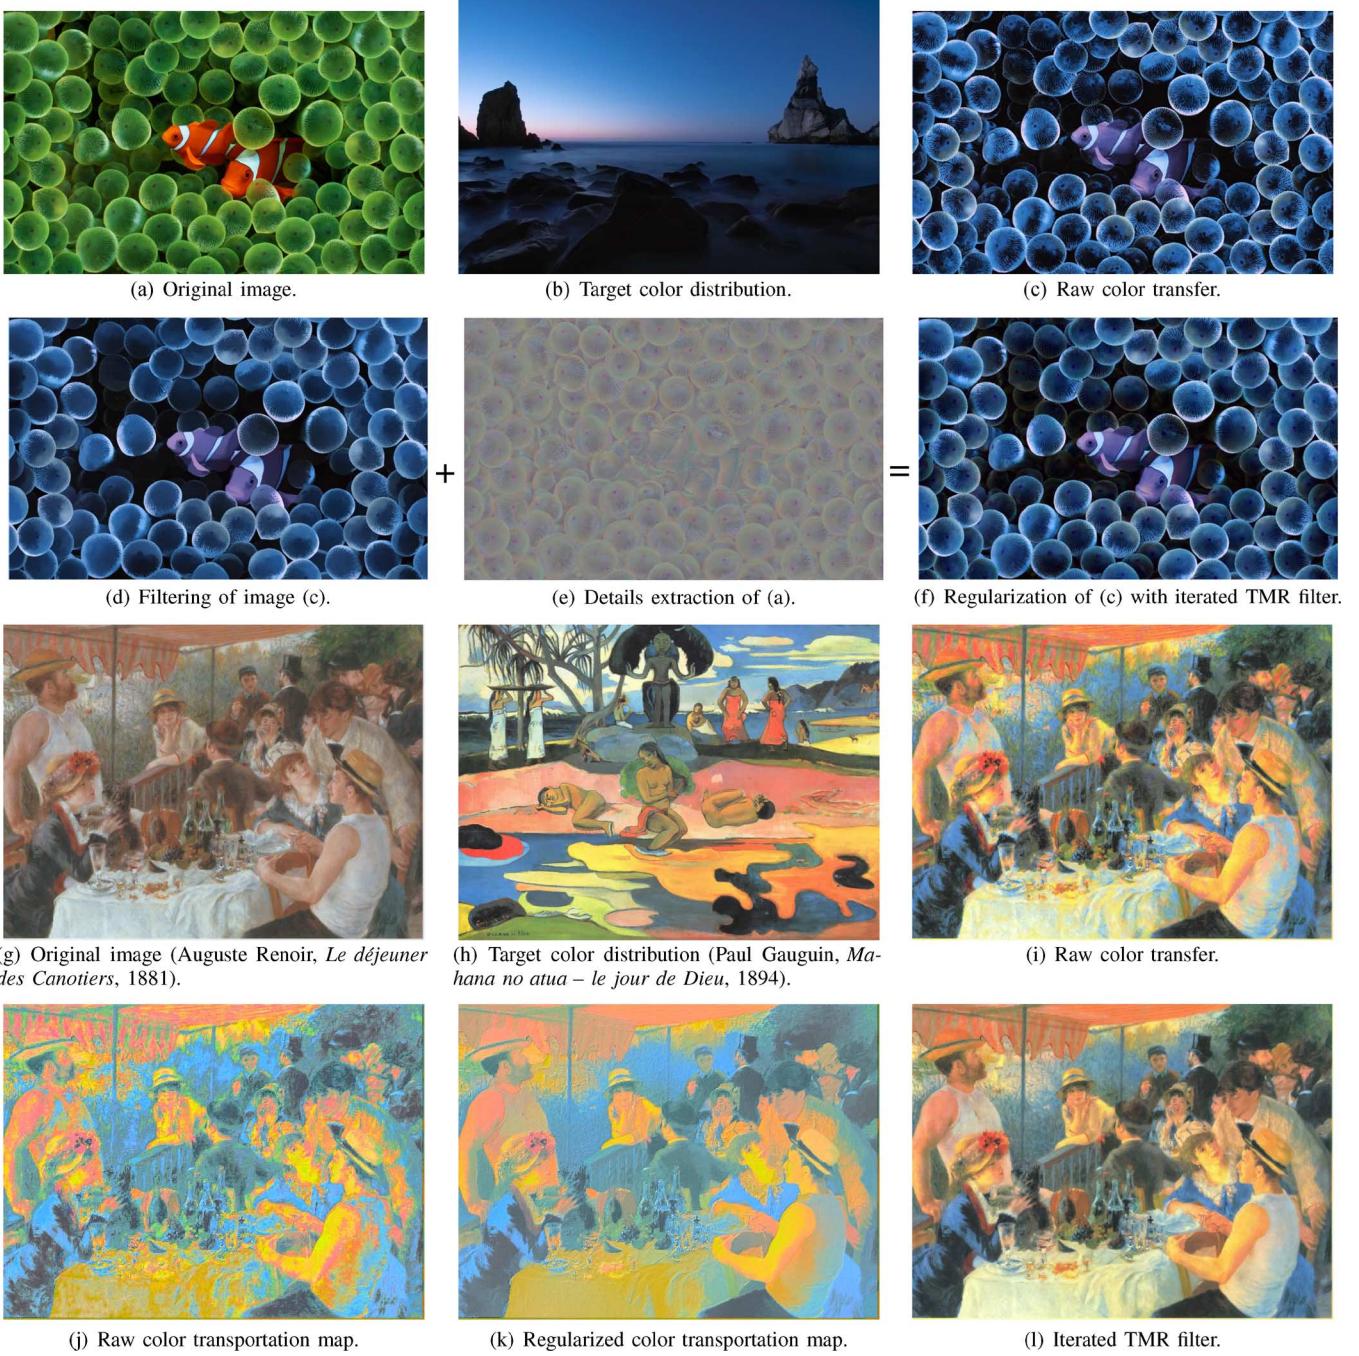

Fig. 6. Illustration of color transfer regularization with iterated TMR filter. The first row displays the result of transferring the colors of (b) to (a). The second row illustrates that the corresponding regularization is obtained as the addition of the filtering of the raw color transfer with the details extracted from the original image, where the mean has been changed for visualization purpose. The third row displays the result of transferring the colors of (h) to (g). The result of the proposed iterated TMR regularization is displayed in (l). One observes that, in contrast with (i), the artefacts due to different color proportions are mostly removed. For illustration, the transportation maps before and after regularization are displayed in (j) and (k), respectively.

resulting in an increase of noise level. The result of the iterated TMR filter is illustrated in Fig. 4(d), using  $\sigma = 4$ . Observe that our approach limits the noise enhancement and maintains the desired contrast modification. It should be noticed that using  $\sigma = 10$  [see Fig. 4(d)] on this example is not satisfying due to the very poor dynamic of the original image [Fig. 4(a)]. This illustrates that the practical choice of the parameter  $\sigma$  may depend on the considered contrast or color modification.

2) *Flicker Reduction*: The proposed regularization scheme can also benefit the restoration of old movies. Fig. 3(a) shows

three images of a sequence suffering from a strong local flicker (fast and unnatural intensity fluctuations from one frame to the other). This sequence is restored by the local method proposed in [12] and the three corresponding restored frames are shown in Fig. 5(b). The method manages to harmonize the local contrast in the sequence. However, as we can see, the flicker and film compression are so brutal that several artefacts appear on some parts of the frames [see, for instance, both heads in the second image and the jacket in the third image in Fig. 5(b)]. Fig. 5(c) shows how these defects are corrected by the iterated TMR filter.

Fig. 7. Illustration of image editing correction with iterated TMR filter. In this example, an image is edited with an image editing software (The Gimp) for color enhancement, using global contrast and saturation modification tools.

**3) Comparison With Other Regularization Approaches:** In the following, we confront our method with other approaches that have been proposed in the literature to reduce irregularities created by contrast modifications.

**Gradient control:** The approach of [18], that has been proposed to enhance the contrast of medical images, consists in applying local histogram equalizations independently on subparts of an image. We return to the images of Fig. 1 to illustrate this point. Fig. 1(c) shows an example where the image has been divided into  $8 \times 8$  overlapping tiles. To prevent the noise level from skyrocketing (in particular in constant regions), the gradient of the transportation map is restricted to a user-defined interval, which also limits the contrast enhancement. In practice, one can observe that artefacts, if still present, are less noticeable than in the classical histogram equalization [Fig. 1(b)]. Fig. 1(h) shows that the iterated TMR filter enables to remove the remaining artefacts while preserving the local contrast changes.

**Two-scale decomposition technique:** Fig. 3(b) shows the result of a *single iteration* of the TMR filter when the mapping  $T$  is an histogram equalization (denoted here by the operator  $\text{EQ}$ ) applied to the image  $u$  of Fig. 1(a). Following (5), the resulting regularized image can be written as  $\text{TMR}_u(\text{EQ}(u)) = Y_u \circ \text{EQ}(u) + u_{\text{details}}$ , where  $u_{\text{details}} = u - Y_u(u)$  is the detail image. This formulation shares similarity with the approach proposed by Durand and Dorsey in [23] in a different context for *tone mapping* (contrast reduction for HDR images). In their framework, the image  $u$  is first decomposed into a base layer using the bilateral filter (corresponding here to  $Y_u(u)$ ) and a detail layer  $u_{\text{details}} = u - Y_u(u)$ . A contrast reduction is then applied to the base layer, and  $u_{\text{details}}$  is added to the result to obtain the final image. Fig. 3(c) demonstrates that this approach, which is well suited for dynamic reduction, is not adapted to contrast enhancement, yielding discontinuities in flat regions.

One can see from Fig. 3(a) how using iterations of the TMR filter until convergence yields an even better result. It is noticeable that this framework shares some common features with the two-scale decomposition approach of [23].

**Regraining:** Another regularization scheme has been proposed by Kokaram *et al.* [5] as a postprocessing for color transfer and can also be used for contrast modification. This scheme relies on a variational formulation combining two fidelity terms: one depending on the gradient of images and the other one on their gray levels. These two terms are weighted by two spatial-adaptive functions, which depend on the gradient

norm of the original image. The result of our implementation of their algorithm on the equalized image  $\text{EQ}(u)$  is shown on Fig. 3(d). Although the visual impact of artefacts is reduced, this method fails to restore completely details, yielding a blurred and “mottled” appearance.

### C. Color Transfer

This section presents the results of our regularization filter on several color transfer examples (see Section II-B). In all of these experiments, the raw color transfer is computed thanks to the algorithm proposed in [5], which is both fast and easy to implement.

**1) Four Examples:** We have already analyzed the color transfer example displayed at the bottom of Fig. 1, which exhibits many artefacts [see details given in Fig. 1(o)–(q)]. Fig. 1(n) shows the result of several iterations of the TMR filter (until the stopping criterion is reached) on this example. As can be observed on the different zooms, the regularization removes all compression artefacts while restoring fine details in the image and reducing color proportion problems.

Two additional examples of color transfer are proposed in Fig. 6. The first one [Fig. 6(a)–(f)] illustrates the two-terms decomposition of (5). Let  $u$  denote the original image [Fig. 6(a)] and  $T(u)$  the same image after color transfer [Fig. 6(c)], using the color palette of Fig. 6(b). Then,  $\text{TMR}_u(T(u))$  [Fig. 6(f)] can be seen as the sum of  $Y_u(T(u))$  [Fig. 6(d)], the filtered version of  $T(u)$ , and  $u - Y_u(u)$  [Fig. 6(e)], which restores the details of the original image  $u$ . In the second example, at the bottom of Fig. 6, the colors of *Mahana no atua* by Gauguin are transferred to the painting *Le Déjeuner des Canotiers*, by Auguste Renoir. The resulting raw transportation map is shown on Fig. 6(j), while Fig. 6(k) and (l) show, respectively, the transportation map and the result of the color transfer after several iterations of TMR filter. Among other effects, the annoying color proportions problems (see, for instance, the blue spots on the white clothes) completely vanish, resulting in a far more plausible image.

A last example is given in Fig. 7 to illustrate the versatility of the proposed approach for various color modification techniques. In this example, the image shown in Fig. 7(a) is modified using an image editing software (The Gimp) to separately increase both the contrast and the saturation of colors. The result of this operation, along with some artefacts, is visible in

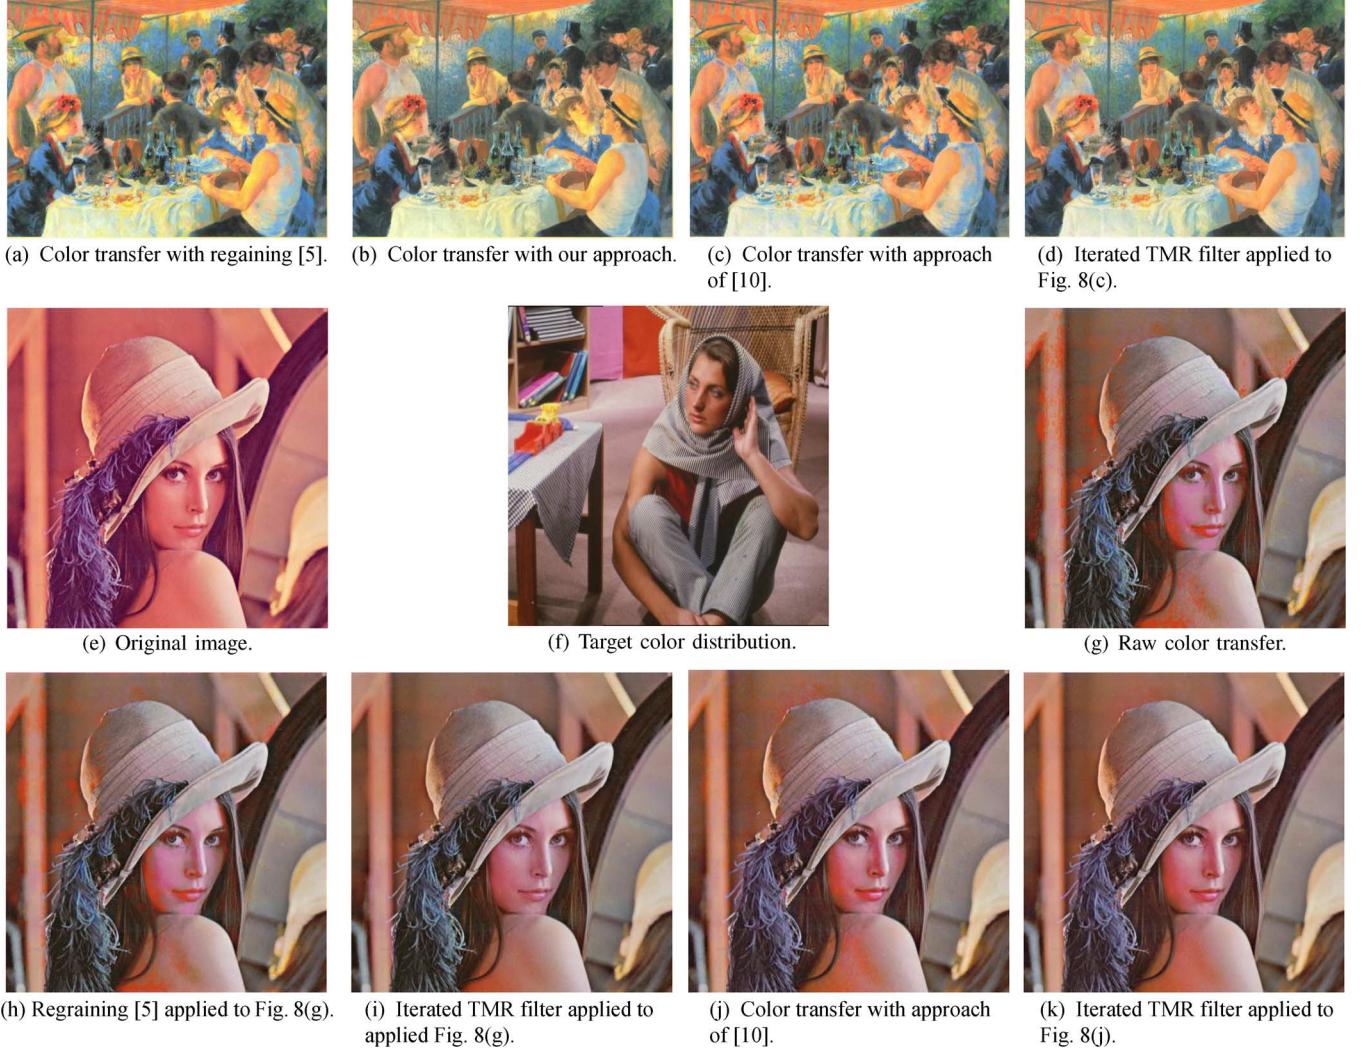

Fig. 8. Comparative color transfer regularization results with regaining approach of [5], iterated TMR filter, and variational histogram equalization of [10]. Original images are shown respectively in Figs. 6(g) and 8(e), with the corresponding target color distribution displayed respectively in Figs. 6(h) and 8(f). Note: These examples and some other ones are available in full resolution at: [http://perso.telecom-paristech.fr/~delon/artefact\\_removal\\_html/](http://perso.telecom-paristech.fr/~delon/artefact_removal_html/).

Fig. 7(b). Again, the proposed method makes it possible to attenuate color blotches and to restore lost details [as can be seen, for example, on the patterns on the roofs in Fig. 7(c)].

2) *Comparison With Other Approaches:* Two results of the regaining approach [5] on the Renoir/Gauguin experiment and on a Lena/Barbara color transfer, are shown, respectively, in Fig. 8(a) and (h). While this variational approach tends to reduce irregularities in the transportation map, it fails at removing severe compression artefacts or inconsistencies in color proportions. As a comparison, the result of the iterated TMR filter on both examples can be seen in Fig. 8(b) and (i).

Another variational approach has been proposed very recently to transfer color between several images while preserving their geometry [10]. This interesting approach enables to perform simultaneously the desired color transfer and its regularization thanks to a unified energy minimization framework, relying on several terms: a quadratic data-fidelity term, a color distribution constraint based on cumulative histograms, and a regularization term preserving the geometry of the images. The result of this approach for the Renoir/Gauguin experiment is

displayed in Fig. 8(c) and for the Lena/Barbara color transfer in Fig. 8(j). Observe that the method achieves the transfer without producing strong artefacts. It is interesting to see that some color inconsistencies are still occurring [Fig. 8(c) and (j)] which are removed with the iterated TMR filter [Fig. 8(d) and (k)].

#### D. Discussion

*Patch-Based Regularization:* Following the idea of the NL-means filter [21], one could think of replacing the pixel-wise comparisons in the TMR filter by patch comparisons. Indeed, in [21], Buades *et al.* show that using small patches instead of pixels increases the confidence level on the similarity measure between pixels corrupted by noise. In our case, it boils down to replacing the weights in (4) by

$$\hat{w}_u(x, y) = \exp \left( -\frac{\sum_{z \in W} \|u(x+z) - u(y+z)\|^2}{n\sigma^2} \right)$$

where  $W$  is a centered square neighborhood defined on the pixel grid, and where  $n$  is the size of  $W$ . Using patches in our frame-

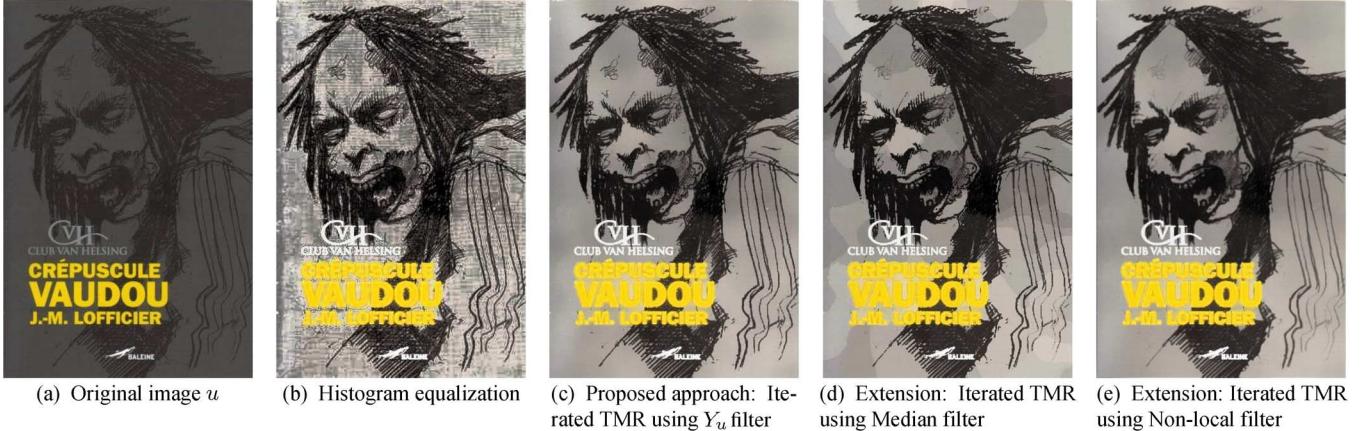

Fig. 9. Variation around TMR filter based on different edge-preserving filters. The same number of iterations (10) and the same parameter setting ( $\sigma = 10$ ) have been used for each experiment.

work does not improve the results (see Fig. 9(e) for a comparison). On the contrary, using the same parameter  $\sigma$ , some fine structures are more blurred (along edges or strokes) with this approach, while some artefacts are less regularized (see the compression artefacts around the book title). Indeed, the use of patches tends to increase the similarity between pixels across edges, so that even some contrasted structures are blurred after several iterations. At the same time, the use of patches tends to decrease the similarity of pixels of non-repetitive structures (see [33] for details), which explains that some artefacts remain. While Yaroslavsky filter is less robust than the NL-means for denoising purposes, it is particularly adapted in our case, where the image  $u$  is regular. It yields a faster approach and a better preservation of edges.

*Median-Based Regularization:* In some cases, it could be interesting to replace Yaroslavsky filter by a median filter. Indeed, the median filter requires only one parameter (the size of the neighborhood), it does not introduce blur and it is able to remove small objects (for instance salt and pepper noise). In the case of contrast modifications, (5) can be rewritten as

$$\text{TMR}_u(T(u)) = \text{Med}_u(T(u)) + u - \text{Med}_u(u)$$

where  $[\text{Med}_u(v)](x)$  is the weighted median of the values  $v(y)$  when  $y$  spans  $\mathcal{N}(x)$ , with weights  $w_u(x, y)/C(x)$ . Fig. 9(d) displays an example of the median based TMR filter. The result presents typical characteristics of median filter approaches, avoiding blurring effects that are inherent to averaging filters, while providing some unsatisfactory piecewise constant regions.

## V. CONCLUSION

In this paper, we have introduced a generic filtering procedure in order to remove the different kinds of artefacts created by radiometric or color modifications. The ability of the proposed TMR filter to deal with these artefacts while restoring the fine details of images has been demonstrated on various examples.

Several extensions of this work are foreseen. First, notice that the computation time of the TMR operator is similar to those of the Bilateral filter [31] or nonlocal means [21]. As a consequence, it could directly benefit from several accelerations techniques that have been proposed recently in the literature for

those type of filters, as for instance, multiscale approximations [34], the use of kd-tree structures for fast computation of pixels comparison [35], or FFT-based convolutions [36]. Second, the whole procedure would also be strengthened by the automatic estimation of the parameters  $\sigma$  and  $\rho$  (for instance, by considering the recent work of [33]), even if most experiments gives satisfactory results running the same parameter values. In particular, when considering movie restoration, those parameters should be set adaptively, depending on the local motion and the local contrast change. Finally, we plan to increase the control of color inconsistencies. Indeed, the approach presented here permits to remove artefacts due to color proportions as long as these are not too extreme. But it cannot completely modify the proportions of colors in the final image. In the case of color transfer, one possible option would be to transfer colors from a precomputed “color palette” [6], [37]. We also believe that the scheme presented in this paper can benefit other applications that color or contrast modifications. One possible framework of application, for which the approach should of course be adapted, is the one of the fusion of panchromatic and multispectral images [38].

## APPENDIX A LINK WITH OPTIMAL TRANSPORT

This section recalls why color and contrast transfers can be seen as optimal transportation problems. As described in Section II-B, assigning a given distribution  $f$  to an image  $u$  boils down to find a mapping  $T$  such that  $h_{T(u)} = f$ . If such mappings exist, one looks generally for one minimizing the global cost

$$\int_{\mathbb{R}^n} \|T(x) - x\|^2 h_u(dx) \quad (8)$$

where  $\|\cdot\|$  is the Euclidean norm. This problem, first stated by Monge in [39], has generally no solution when  $h_u$  is discrete. Kantorovich proposed to relax the problem into a more general one, where one looks for a probability distribution  $\pi$  on  $\mathbb{R}^n \times \mathbb{R}^n$ , with marginals  $h_u$  and  $f$  (we write  $\Pi(h_u, f)$  the set of these probability measures, which are called transportation plans). Observe that  $\pi$  can be seen as a multivalued function sending exactly  $h_u$  onto  $f$ . Among all transportation plans in

$\Pi(h_u, f)$ , one imposes that  $\pi$  minimizes a global transportation cost

$$\int_{\mathbb{R}^n \times \mathbb{R}^n} \|x - y\|^2 \pi(dx \times dy). \quad (9)$$

In practice, a satisfying mapping  $T$  between  $h_u$  and  $f$  can then be chosen as one approximating the optimal plan  $\pi$ . If we apply this framework to the case  $n = 1$ , we find formulas similar to (3) for histogram equalization and specification.

## APPENDIX B POWERS OF STOCHASTIC MATRICES

Here, we recall the Perron–Frobenius theorem as it is stated in [40], [41]. Recall that a square matrix  $A$  is said to be *primitive* if there exists  $q \in \mathbb{N}^*$  such that  $A^q$  is strictly positive, in the sense that all coefficients  $A_{i,j}^q$  are strictly positive.

*Theorem 1 (Perron–Frobenius, See [40], [41]):* Let  $A$  be a nonnegative primitive  $m \times m$  matrix. There exists a real eigenvalue  $\lambda_1$  with algebraic as well as geometric multiplicity one such that  $\lambda_1 > 0$ , and  $\lambda_1 > |\lambda_j|$  for any other eigenvalue  $\lambda_j$ . Moreover, the left eigenvector  $\pi_1$  and the right eigenvector  $l_1$  associated with  $\lambda_1$  can be chosen positive and such that  $\pi_1^T l_1 = 1$ . Let  $\lambda_2, \lambda_3, \dots, \lambda_m$  be the eigenvalues of  $A$  other than  $\lambda_1$  ordered in such a way that  $\lambda_1 > |\lambda_2| \geq \dots \geq |\lambda_m|$  and if  $|\lambda_2| = |\lambda_j|$  for some  $j \geq 3$ , then  $m_2 \geq m_j$ , where  $m_j$  is the algebraic multiplicity of  $\lambda_j$ . Then

$$A^r = \lambda_1^r l_1 \pi_1^T + O(r^{m_2-1} |\lambda_2|^r) \quad (10)$$

where  $O(f(r))$  represents a function of  $r$  such that there exists  $\alpha, \beta \in \mathbb{R}$ ,  $0 < \alpha \leq \beta < \infty$ , such that  $\alpha f(r) < O(f(r)) < \beta f(r)$  for all  $r$  sufficiently large.

*Proof:* See [41].

Observe that the matrix  $A$  defined in Section III-C is stochastic, which implies that  $\lambda_1 = 1$  and  $l_1 = (1, 1, \dots, 1)^T$ . All of the lines of  $A^\infty$  are thus equal to the left eigenvector  $\pi_1$  for the eigenvalue 1. Now, if the neighborhood  $\mathcal{N}(0)$  is symmetric (which implies that  $i \in \mathcal{N}(j)$  if and only if  $j \in \mathcal{N}(i)$ ), this left eigenvector is

$$\pi_1(i) = \left( \sum_{j=1}^m w_u(i, j) \cdot \mathbf{1}_{j \in \mathcal{N}(i)} \right) / \left( \sum_{k, j=1}^m w_u(k, j) \cdot \mathbf{1}_{j \in \mathcal{N}(k)} \right)$$

where exponential weights  $w_u$  are defined in (4). The limit matrix can thus be computed easily in this case.

## APPENDIX C STOCHASTIC MATRICES WITH STOPPING CRITERION

Here, we show that, if  $A$  is the matrix defined in Section III-C, and if  $B$  is built by replacing some lines in  $A$  by the same lines in the identity matrix, then the sequence  $(B^k)$  still converges toward a limit matrix  $B^\infty$ . This property is a consequence of classical results and the proof is provided for the sake of completeness.

First, observe that there exists a permutation matrix  $\Sigma$  such that  $B' = \Sigma B \Sigma^{-1}$  can be written as

$$\begin{pmatrix} I_r & \mathbf{0}_{r \times (m-r)} \\ R & Q \end{pmatrix} \quad (11)$$

where  $I_r$  is the identity matrix of size  $r$ ,  $\mathbf{0}_{r \times (m-r)}$  is the null matrix of size  $r \times (m-r)$ ,  $R \in \mathcal{M}_{m-r, r}(\mathbb{R})$  and  $Q \in \mathcal{M}_{m-r}(\mathbb{R})$ . Since  $B^k = \Sigma^{-1} B'^k \Sigma$ , the convergence of the sequence  $(B'^k)$  will imply the convergence of  $(B^k)$ , so we assume in the following that  $B$  is written as in (11). Now

$$B^k = \begin{pmatrix} I_r & \mathbf{0}_{r \times (m-r)} \\ R_k & Q^k \end{pmatrix}, \text{ with } R_k = \left( \sum_{j=0}^{k-1} Q^j \right) R \quad (12)$$

and the study of the sequence  $(B^k)$  boils down to the study of the sequence  $(Q^k)$ .

Now, observe that the sequence  $\sum_{j=1}^{m-r} (Q^k)_{i,j} = \sum_{j=r+1}^m (B^k)_{i+r,j}$  decreases with  $k$ , for all  $1 \leq i \leq m-r$ . Indeed, since  $B$  is stochastic, for all  $i$ , then

$$\sum_{j=1}^{m-r} (Q^{k+1})_{i,j} = \sum_{j=1}^{m-r} \sum_{l=1}^{m-r} (Q^k)_{i,l} Q_{l,j} \leq \sum_{l=1}^{m-r} (Q^k)_{i,l}.$$

Moreover, for each line  $i \leq m-r$ , there exists a rank  $k_0$  such that, for all  $k \geq k_0$ ,  $\sum_{j=1}^{m-r} (Q^k)_{i,j} < 1$ . Indeed, the set  $\mathcal{C}$  of points which have already converged is not isolated in the image. Step by step, each point outside of  $\mathcal{C}$  (indexes  $\{r+1, \dots, m\}$  in  $B$ ) undergoes the influence of at least one point of  $\mathcal{C}$  (indexes  $\{1, \dots, r\}$  in  $B$ ) after a large enough number of iterations, which implies that for all  $i \in \{r+1, \dots, m\}$ , there exists  $k_0$  and  $j \in \{1, \dots, r\}$  such that  $R_k(i, j) > 0$  for  $k \geq k_0$ .

The index  $k_0$  can be chosen such that this property holds for all  $i \in \{1, \dots, m-r\}$ . Since these sequences are decreasing, there exists  $\gamma$  in  $]0, 1[$  such that for all  $i$  and all  $k > k_0$ ,  $\sum_{j=1}^{m-r} (Q^k)_{i,j} < \gamma$ . Thus, for each  $p \in \mathbb{N}^{+*}$ , we have

$$\begin{aligned} \sum_{j=1}^{m-r} (Q^{pk+k})_{i,j} &= \sum_{j=1}^{m-r} \sum_{l=1}^{m-r} (Q^{pk})_{i,l} (Q^k)_{l,j} \\ &\leq \gamma \sum_{l=1}^{m-r} (Q^{pk})_{i,l} < \gamma^{p+1}. \end{aligned}$$

It follows that  $\sum_{j=1}^{m-r} (Q^{pk})_{i,j} \xrightarrow[p \rightarrow \infty]{} 0$ . This property also holds for the whole sequence  $\sum_{j=1}^{m-r} (Q^k)_{i,j}$  since it is decreasing with a subsequence converging to 0. Since all the coefficients of these matrices are positive, we conclude that  $Q^k \xrightarrow[k \rightarrow \infty]{} 0$ .

Now, notice that  $R_k = (\sum_{j=0}^{k-1} Q^j) R = (I - Q)^{-1} (I - Q^k) R$  (if  $I - Q$  was not invertible, then we would have  $x \neq 0$  such that  $Qx = x$  which is impossible since  $Q^k \xrightarrow[k \rightarrow \infty]{} 0$ ). Thus,  $R_k \xrightarrow[k \rightarrow \infty]{} (I - Q)^{-1} R$ . Finally

$$B^k \xrightarrow[k \rightarrow \infty]{} \begin{pmatrix} I_r & \mathbf{0}_{r \times (m-r)} \\ (I - Q)^{-1} R & \mathbf{0}_{(m-r) \times (m-r)} \end{pmatrix}. \quad (13)$$

## ACKNOWLEDGMENT

The authors would like to thank A. Márques for his work on flicker experiments and N. Papadakis for providing his code. The authors would like also to thank G. Peyré for fruitful comments and discussions.

**Julien Rabin** received the M.S. degree from the École Normale Supérieure de Cachan, France, in 2006, and the Ph.D. degree in signal and image processing from Télécom ParisTech, Paris, France, in 2009.

After working as a Postdoctoral Researcher with the Paris Dauphine University France, in 2010, he joined the École Normale Supérieure de Cachan for a postdoctoral position. His research interests are image enhancement, optimal transportation, and object and shape recognition.

**Julie Delon** received the M.S. degree and Ph.D. degree in applied mathematics from the École Normale Supérieure de Cachan, France, in 2001 and 2004, respectively.

She has been a CNRS Researcher with Télécom ParisTech, Paris, France, since 2005. Her research interests include the mathematical modeling of images, optimal transportation, film restoration, and image processing.

**Yann Gousseau** received the M.S. degree from the École Centrale de Paris, Paris, France, in 1995, and the Ph.D. degree in applied mathematics from the University of Paris, Dauphine, France, in 2000.

After working as a Postdoctoral Researcher with Brown University, Providence, RI, and with the École Normale Supérieure de Cachan, France, he joined Télécom ParisTech, Paris, France, where he has been an Associate Professor since 2001. His research interests include the mathematical modeling of natural images, image analysis, computer vision, and image processing.
